Abstract

Exploring elevational patterns in species richness and their underlying mechanisms is a major goal in biogeography and community ecology. Reptiles can be powerful model organisms to examine biogeographical patterns. In this study, we examine the elevational patterns of reptile species richness and test a series of hypotheses that may explain them. We sampled reptile communities along a tropical elevational gradient (100–1,500 m a.s.l.) in the Western Ghats of India using time-constrained visual encounter surveys at each 100-m elevation zone for 3 years. First, we investigated species richness patterns across elevation and the support of mid-domain effect and Rapoport's rule. Second, we tested whether a series of bioclimatic (temperature and tree density) and spatial (mid-domain effect and area) hypotheses explained species richness. We used linear regression and AICc to compare competing models for all reptiles, and each of the subgroups: snakes, lizards, and Western Ghats' endemics. Overall reptile richness and lizard richness both displayed linear declines with elevation, which was best explained by temperature. Snake richness and endemic species richness did not systematically vary across elevation, and none of the potential hypotheses explained variation in them. This is the first standardized sampling of reptiles along an elevational gradient in the Western Ghats, and our results agree with the global view that temperature is the primary driver of ectotherm species richness. By establishing strong reptile diversity–temperature associations across elevation, our study also has implications for the impact of future climate change on range-restricted species in the Western Ghats.

1 | INTRODUCTION

Why are there different numbers of species in different places? The answer to this question is a major goal in ecology and biogeography (Brown, 2014; MacArthur, 1972; Pianka, 1966). Exploring

this question provides us with a greater understanding of how the natural world is organized, but is also a critical activity in a range of conservation planning contexts (Pimm & Brown, 2004; Ricketts et al., 1999). This aim is increasingly important as we enter the Anthropocene, and species must either move or evolve if they are

to survive (Pech et al., 2017). Numerous studies across the globe are describing patterns of species diversity and testing them against mechanistic hypotheses (Hudson et al., 2014; Peters et al., 2016). Despite this effort, however, our understanding of species diversity patterns is taxonomically and geographically biased—focussing on patterns of bird and mammal diversity in Europe and the Americas (Hudson et al., 2014). To address this, we explore the variation in species richness of reptiles along an elevational gradient in one of the world's "hottest biodiversity hot spots": the Western Ghats (Myers et al., 2000; Nair, 1991).

Mountain regions contain disproportionate numbers of species relative to their geographic area (Rahbek, et al., 2019), and many of the global biodiversity hot spots exist within them (Guo et al., 2013; Kozak & Wiens, 2010). In terms of understanding general mechanisms underlying variation in species diversity, elevational gradients have long been recognized as useful "microcosms" of broader latitudinal patterns in species richness (Stevens, 1992). Latitudinal gradients themselves are challenging to study due to their large spatial extent, but in the case of elevational gradients, individual mountain ranges can act as replicated transects. This provides opportunities to test the underlying causes of species diversity patterns (Sanders & Rahbek, 2012). Finally, while elevational gradients have a wide diversity of topographies and climates (Rahbek, et al., 2019), a key feature of them is the existence of a strong thermal gradient. Temperature, a factor known to influence the distribution and functioning of life across organizational scales (Brown, 2014), universally declines with increasing elevation. Temperature is particularly important for reptiles; as ectotherms, they rely on ambient temperature to regulate their body heat and allow them to function (Angilletta, 2009).

Elevational patterns in species richness tend to take one of three main forms: (a) a monotonic increase, (b) a monotonic decline, and (c) a mid-elevational peak (Rahbek, 1995). The prevalence of these patterns can vary across different taxonomic groups and biogeographical regions (Peters et al., 2016), although the hump-shaped, mid-elevational peak is reported to be the most common relationship (Rahbek, 2005). There are several hypotheses that may explain these different richness–elevation patterns, and these can be broadly grouped into two main categories: bioclimatic or spatial hypotheses (Grytnes & McCain, 2007).

Variation in biologically important variables such as temperature, rainfall, or productivity represents climatic hypotheses. In these cases, it is hypothesized that the covariation of these factors along elevational gradients is the cause for various richness–elevation patterns. Compared with endotherms, ectotherm metabolism is highly dependent on ambient temperature (Angilletta, 2009). In consequence, declines in ectotherm richness along elevational gradients have been repeatedly linked to concurrent declines in temperature across space and time (Bishop et al., 2014; Peters et al., 2016), and these patterns can further be explained by the availability of water (Szewczyk & McCain, 2016).

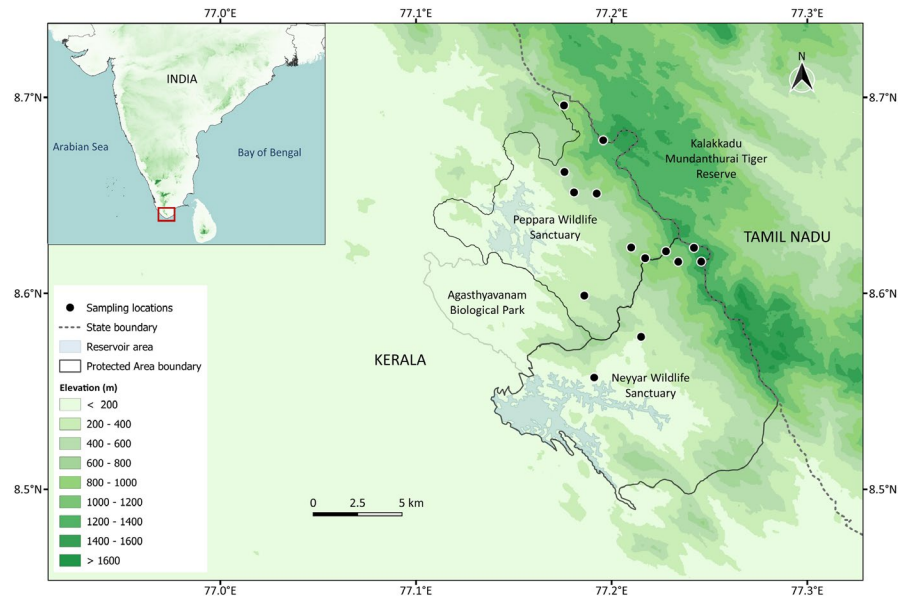

The second category of hypotheses seeking to explain elevational gradients in species richness is spatial. A common explanation for richness–elevation patterns is the influence of available area

(Lomolino, 2001). This hypothesis is analogous to the well-known species–area relationship, which suggests that more individuals will exist in elevational zones that have more available area, which in turn are more likely to come from a larger species pool (Romdal & Grytnes, 2007; Sanders, 2002). The mid-domain effect (MDE) is another popular spatial hypothesis describing species richness patterns. The MDE predicts mid-elevational peaks in richness, purely as a result of the geometry of a bounded domain, such as that between a mountain top and the coast (Colwell & Hurtt, 1994; Colwell & Lees, 2000; Jetz & Rahbek, 2001). Through the random placement of varying species ranges, there is a high probability of greater range overlap, and therefore higher species richness, at the center of the bounded domain (Colwell & Lees, 2000). Thus, the MDE is purely a geometric constraint hypothesis—although recent analyses have modeled this effect in conjunction with bioclimatic variables (Colwell et al., 2016). There is mixed empirical support for the influence of MDE on elevation–richness patterns (Currie & Kerr, 2008; Hawkins & Diniz-Filho, 2002; McCain, 2009).

Rapoport's rule on elevational range sizes can also be seen as a "spatial" hypothesis (Stevens, 1992), although it derives from some degree of climatic control (Kendall & Haedrich, 2006). Rapoport's rule hypothesizes that species at higher elevations have larger range sizes than those at lower elevations. This is due to the broader climatic tolerances required to survive in variable high-elevation conditions. There is an underlying assumption that most species have relatively small ranges and cannot tolerate a broad range of climatic conditions. Consequently, ranges accumulate in the climatically stable lowlands to generate a monotonic decline in species richness with increasing elevation (Rahbek, 1997; Stevens, 1992). Like the MDE, support for Rapoport's rule as a general phenomenon is mixed (Gaston & Chown, 1999; McCain & Knight, 2013; Sanders, 2002).

In this study, we are interested in describing and understanding the elevational diversity patterns of reptiles in the Western Ghats of India. Overall, richness–elevation patterns of herpetofauna (reptiles and amphibians) tend to show monotonic declines (Cadle & Patton, 1988; Chettri et al., 2010; Heatwole, 1982; Hofer et al., 1999, 2000; Nathan & Werner, 1999; Woinarski & Gambold, 1992). This taxonomic group is largely understudied within India especially on elevational diversity patterns (but see Chettri et al., 2010; Naniwadekar & Vasudevan, 2007). This demands immediate attention because the Indian subcontinent, and the Western Ghats in particular, is a global hot spot of biodiversity. The unique bioclimatic conditions, topographic features, and habitat heterogeneity make the Western Ghats particularly rich in biodiversity and high in species endemism (Myers et al., 2000; Nair, 1991). Particularly, 47% of the reptiles that occur here are endemic to the Western Ghats (Srinivasulu et al., 2014). Recent studies have also indicated that each mountain range in the Western Ghats possibly has many local endemics and basal lineages—especially in case of reptiles (Chaitanya et al., 2019; Cyriac et al., 2018; Deepak et al., 2020; Mallik et al., 2019; Pal et al., 2018). Consequently, there is a need to better document and explain patterns of species richness in this region.

FIGURE 1 Sampling locations along the elevational gradient in Agasthyamalai Hills. Inset: location of the study area in the Indian subcontinent

In this context, we ask the following questions: (a) How is reptile species richness distributed across elevation in the southern Western Ghats?; And (b) what bioclimatic and spatial hypotheses explain these patterns? We use temperature and tree density as measures of bioclimatic niche variables of relevance to reptiles. We predict that both will relate positively to reptile species richness in this region: Reptile metabolism is tightly linked to ambient temperature, and we hypothesize that higher tree densities will provide a greater number of niches that different reptile species can exploit. Tree density is often used as a surrogate of habitat heterogeneity and habitat complexity (McCoy & Bell, 1991) and has been repeatedly shown to alter reptile community structure (Gillespie et al., 2015; Heyer & Berven, 1973; Scott, 1976; Voris, 1977). In our case, we hypothesize that more reptiles will be present in areas of higher tree densities.

We test each hypothesis separately for the two main subgroups of reptile: snakes and lizards. This is typically done in studies of reptile diversity (Chettri et al., 2010; Fu et al., 2007; Kryštufek et al., 2008) because of their different morphology and life-history strategies (Shine & Charnov, 1992). Snakes tend to occupy higher trophic positions compared with lizards, and move through the environment very differently as they do not have legs (Gove, 1979; Parker & Plummer, 1987). Furthermore, snakes tend to have larger range sizes compared with lizards, which may be an indication of their higher dispersal abilities (Böhm et al., 2013). In general, large-ranged and small-ranged species tend to show different responses to the mid-domain effect (Dunn et al., 2006, 2007), with small-ranged taxa less likely to conform to the predictions of the MDE.

In this context, we predict that the differences in life-history strategies and range sizes between snakes and lizards will result in different elevation–richness patterns, specifically that snakes, with their larger ranges, will be more likely to conform to a mid-elevational peak. We also predict that endemic species will show a mid-elevational peak or a monotonic increase in richness with elevation.

Previous studies on herpetofauna have found mid-elevational peaks in endemic richness (Fu et al., 2006), while globally, increases in endemism with elevation may be explained by the greater topographic isolation of these areas, which promotes speciation and endemism (Steinbauer et al., 2016). Finally, given previous work on reptiles, which found limited global support for a series of spatial hypotheses (McCain, 2010), we expect to find more support for climatic hypotheses at this local scale in the Western Ghats. Simultaneous tests of these hypotheses have not yet been undertaken for reptiles in the biodiversity hot spot of the Western Ghats. Here, we provide a test.

2 | METHODS

2.1 | Study area

Our study was located within the Agasthyamalai Hills (8°4' to 8°8'N, 77°0' to 77°4'E), which is part of the Agasthyamalai Biosphere Reserve (ABR) on the southern tip of the Western Ghats. We covered only the western slope (windward side) of the Agasthyamalai Hills, which comprised of two major protected areas: Neyyar and Peppara wildlife sanctuaries in the Kerala State (Figure 1). The mean temperature of the coldest month in the region ranges from 13 to 23°C (Pascal, 1982). The windward side of the Agasthyamalai Hills receives high rainfall: varying between 2,000 and 5,000 mm annually with only two to three dry months (Ramesh et al., 1997; Varghese & Balasubramanyan, 1999).

The Agasthyamalai region is well known for its high plant diversity and endemism (Manju et al., 2009; Nayar, 1996; Ramesh et al., 1997). The vegetation of the area changes significantly along elevation. Champion and Seth (1968) identified four major vegetation types in the area: southern moist mixed deciduous forest (<400 m a.s.l.), west coast semi-evergreen (400–600 m a.s.l.), west coast tropical evergreen (600–1,200 m a.s.l.) and southern hilltop

tropical evergreen (>1,200 m a.s.l.). The deciduous or evergreen forests up to 1,200 m a.s.l. are comprised of taller trees with canopy height ranging from 10 to 35 m; however, the hilltop forest is of a dense, stunted evergreen type with canopy height reaching a maximum up to 10 m, mixed with open rocky and grass areas (Varghese & Balasubramanian, 1999). Apart from human settlements in the lower elevations (<400 m a.s.l.), trekking and pilgrimage activities also exert significant pressure on the natural habitats of the region (Ramesh et al., 1997). Although we observed some level of habitat disturbance along the main trekking route, our sampling was mostly restricted to undisturbed patches along the elevational gradient.

The focal study area encompasses approximately 250 km², spread across an elevational range of 50 to 1,868 m a.s.l. The coast is 30 km from the site—this makes the landscape ideal for testing mid-domain effects as it has geometric constraints on both ends, the mountain summit at the top and the coastline at the bottom.

2.2 | Data collection

2.2.1 | Reptile richness

We surveyed reptiles in the Agasthyamalai Hills from April 2012 through to December 2014 along an elevational gradient, covering both wet and dry seasons. The total elevational range was categorized into fourteen 100-m-wide elevational bands, beginning at 100 m a.s.l. and rising to 1,500 m a.s.l. We did not sample at the coast due to the lack of adequate undisturbed habitat, and we did not sample higher than 1,500 m a.s.l. due to logistical constraints. Transects of approximately 2,000 m in length and 250–300 m in width were laid in each elevational band based on topography and accessibility. We performed time-constrained visual encounter surveys (VES) to sample the reptile communities in each elevational band. The VES method surveys an area for a prescribed time, systematically searching for animals in all possible microhabitats covering different vertical strata (Campbell & Christman, 1982; Crump & Scott, 1994). This is an appropriate and well-understood method for both species inventorying and monitoring, and is suitable for examining landscape-level patterns especially in mountains. The method is also known for having a higher detection rate of rare species (Crump & Scott, 1994) and has successfully been applied before in the Western Ghats (Bhupathy & Nixon, 2011) and Eastern Himalayas (Chettri et al., 2010).

We used the transects laid in each elevational band as an approximate spatial guide for our VES sampling. We gradually searched along each transect for reptiles using VES during daylight, between 08:00 and 18:00 hr, and the search included turning stones and fallen logs, moving leaf litter, scanning the vegetation, and searching on stems and barks of trees. In this sense, VES explores all possible microhabitats from the ground level to the tree branches of approximately 3 m above the ground. Even though active microhabitat search was not possible in higher vertical strata (above 3 m), simple visual scanning of vegetation and tree branches to a maximum height was carried out wherever possible. Repetition of sampling in

the same spatial area was avoided as the VES method involves the alteration of microhabitats (turning stones and logs etc.). In our dataset, a single VES “sample” within an elevational band consisted of two person-hours (1-hr × 2 people searching = 2 person-hours). We were unable to perform equal sampling effort across the elevations, however, due to the differences in spatial and temporal accessibility to some elevational zones (Table S1). We identified all reptiles to species level where possible and assigned a distinct morphospecies identifier where full identification was not possible.

2.2.2 | Tree density

We laid 10 × 10 m quadrats along each elevational transect, each quadrat separated by 250 m. This gave eight quadrats on most transects, although space constraints restricted us from laying eight quadrats at all elevations. All elevations had at least four quadrats. We counted the number of trees in each quadrat to estimate tree density per hectare.

2.2.3 | Elevation and available area

Elevation for each VES was determined during the sampling using an altimeter and GPS. We extracted ASTER global digital elevation model version 3 (source: <https://earthdata.nasa.gov/>, downloaded on 10 January 2020) and calculated the available area of each 100-m elevational band using QGIS version 3.10. Only the western slope of the Agasthyamalai Hills was considered for this area calculation as it comprises the entire area of the study.

2.2.4 | Environmental variables

We downloaded bioclimatic variables for the study area from the Chelsa climatic data base (<http://www.chelsa-climate.org/>), which is a fine-scale (i.e., 1 × 1 km), long-term (1979–2013) climate dataset with global coverage based on statistical downscaling (Karger et al., 2017). Due to its high resolution, the Chelsa dataset is reported to be more effective for modeling species distributions in geographically complex regions such as mountainous landscapes (Maria & Udo, 2017). Out of the available 19 bioclimatic variables, we retained only mean annual temperature (MAT) and mean annual precipitation (MAP) for analysis as they are most ecologically important for the distribution of reptiles. QGIS version 3.10 was used for extracting the data from the bioclimatic layer, and we used the central point of each elevational transect to represent the climate of each elevation.

2.3 | Data analysis

All analyses took place within the R environment (R Core Team, 2018).

2.3.1 | Species richness

We used rarefaction to generate standardized species richness estimates because sampling effort (hours of VES) varied across the elevational bands. We used the *iNEXT* package in R (Hsieh et al., 2016) to do this. Specifically, we used the function *estimateD* in “incidence_freq” mode (because our raw data are incidences of species in variable numbers of samples from each elevation). We used *estimateD* to estimate species richness for each elevation at the median sampling effort (38 two person-hours). This involved extrapolating richness estimates for elevations that were not sampled for 38 two person-hours, and interpolating samples that were sampled for more than 38 two person-hours. We employed this procedure using four different data subsets: reptiles (all species), snakes, lizards, and endemics (of the Western Ghats). We use these estimated species richness values in all the analyses that follow. We assigned the status of endemism of each species based on a recent assessment of reptiles of the Western Ghats (Srinivasulu et al., 2014). We provide sample completeness estimates from *iNEXT* in Table S1.

2.3.2 | Describing elevational patterns

We used linear regressions with Gaussian errors to test whether the species richness of each taxonomic subset had a linear, curvilinear or no relationship with elevation. We used Gaussian errors because the sample size-corrected species richness values were not integers. For the linear models, we used only elevation as a predictor variable. For the curvilinear models, we used elevation and elevation² as predictor variables. The null models included only an intercept. We compared models using bias-corrected Akaike information criteria (AICc). We calculated the difference in AICc (ΔAICc) between the three models, relative to the one with the lowest AICc, and extracted R^2 adjusted for small sampled sizes. Where competing models are within 2 ΔAICc of each other, we opt to interpret and present the simplest model. We present the model with the lowest AICc along with its adjusted R^2 for each taxonomic subset. None of the models deviated from the model assumptions based on our interpretation of the model diagnostic and residual plots.

2.3.3 | Testing species richness drivers

We use an information-theoretic approach to assess the relative evidence for different hypothesized drivers of variation in reptile species richness (Burnham & Anderson, 2002). We did not build a “global model” and analyze all possible submodels. Rather, we split our explanatory variables into three classes representing separate, competing hypotheses, and ranked them using AICc. We did this because we do not consider models containing MDE along with other explanatory variables to be biologically meaningful—these hypotheses operate at completely different spatiotemporal scales

to those concerning temperature or precipitation, for example. Our goal was to assess the relative weight of evidence in favor of a given hypothesis (represented by one or more actual statistical models). These classes were environmental, area, and mid-domain effects (MDE). Plots of their variation across elevation are presented in Figure S1.

Environmental drivers

We used mean annual temperature (°C) and tree density (n/ha) to represent environmental drivers. We did not include precipitation because models containing precipitation, and temperature and tree density, had variance inflation factors (VIF) above 2 (Fox & Monette, 1992). In total, there were three environmental models: temperature, tree density, and temperature + tree density. We hypothesized that each variable may positively influence reptile species richness independently, or in combination.

Area

We used available elevational area (as described above) to represent the species–area hypothesis.

Mid-domain effect

For MDE, we used the R package *rangemodLR* (Marathe, 2019) to simulate artificial, random range distributions 1,000 times. We took the average species richness estimate across the repetitions as the prediction of the MDE hypothesis. This package uses the approach of Wang and Fang (2012), itself an extension of the classic MDE model of Colwell et al. (2004). This model shuffles range midpoints while maintaining range sizes. Midpoints can be shuffled anywhere within the geometric constraints of a bounded domain. We used this procedure separately for each taxonomic subset. Species ranges were interpolated between the highest and lowest elevations we observed them, species recorded at only a single elevation were given a range size of 0.

We modeled each class of drivers separately (1 model for each class, except for the environmental class where there were three candidate models). We constructed linear regressions with Gaussian errors to do this. We compared and ranked all models, including the null intercept only model, using AICc and calculated adjusted R^2 values. We consider the “best” model to be the one with the lowest AICc, but also interpret models within 2 ΔAICc of the top-ranked model. We also interpret our models considering the size and direction of the effect sizes (by standardizing all explanatory variables prior to running the regressions) (Schielzeth, 2010) and the proportion of variance explained (R^2). For example, models for the MDE hypotheses should have a slope of ~ 1 if they are predicting similar richness–elevation patterns to our observed data. We performed this modeling procedure four times, once for each of the taxonomic subsets of all reptiles, snakes, lizards, and endemic species.

Finally, we tested Rapoport's rule by correlating species range sizes with their range midpoints (Kwon et al., 2014). We interpolated species ranges, assuming them to be present at all elevations

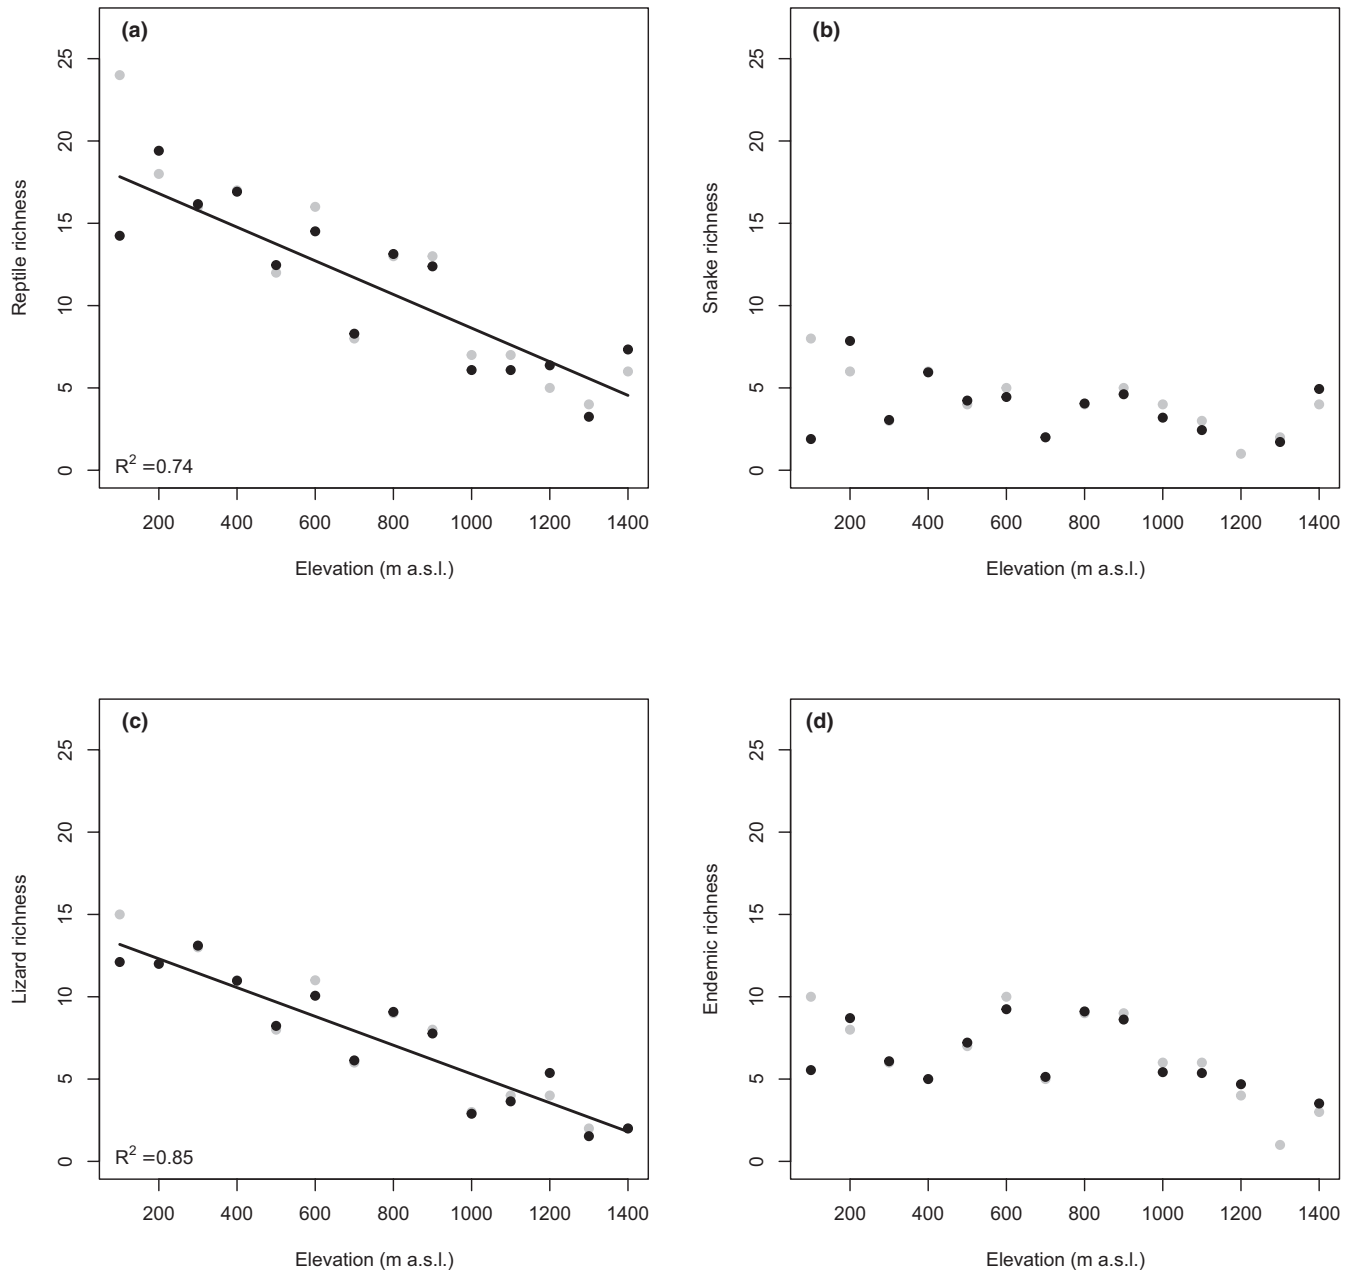

FIGURE 2 Patterns of species richness across elevation for (a) all reptiles, (b) snakes, (c) lizards, and (d) endemic species. Data points represent elevational sampling sites. Black points are the analyzed data, interpolated or extrapolated to correct for sampling biases. Gray points represent the raw, observed species richness values. Lines represent linear regression lines

between the highest and lowest observed sighting to generate these data. We performed this test for each subset of reptiles: all, snakes, lizards, and endemics.

3 | RESULTS

We sampled 47 species of reptiles across the elevational gradient, including 24 lizards, 22 snakes, and one tortoise. Of them, 25 species are endemic to the Western Ghats. Our full dataset and R code are made available in the public data archiving platform, Dryad.

3.1 | Elevational patterns

For reptiles and lizards, species richness declined linearly with increasing elevation (Figure 2a,c; $\Delta AICc$ to next best model was 3.99 and 3.86, respectively). In each case, elevation explained a large fraction of the variation in species richness (reptiles' adjusted $R^2 = .74$; lizards' adjusted $R^2 = .85$). Neither the linear or curvilinear models fitted well to the patterns of snake and endemic species richness, suggesting that there was no clear systematic variation of species richness with elevation in these groups (Figure 2b,d; $\Delta AICc$ to next best model was 2.46 and 1.56, respectively). Full model details can be found in Table S2.

3.2 | Species richness drivers

The best-supported models explaining overall reptile species richness were those for temperature and temperature + tree density (Table 1). Temperature was positively related to reptile species richness, while tree density showed a weaker but negative relationship (Figure 3a,b). The inclusion of tree density did not explain any additional variance compared with the model containing only temperature: Its ΔAICc was greater than 2, and the standardized slope was much smaller than that of temperature in the same model (Table 1).

None of the tested hypotheses appears to drive snake species richness (Table 1). The best model was the one containing only an intercept, and none of the candidate models had high R^2 values (expanded version of Table 1 in the supplementary material, Table S3).

For lizard species richness, temperature was the clear best model (Table 1). Lizard species richness was positively related to temperature (Figure 3c). The model containing temperature + tree density was ranked second, but, again, the inclusion of this variable did not increase the R^2 and the AICc values indicated that this model was poorer than the one containing only temperature (Table 1). Furthermore, the slope estimate for tree density was smaller than that for temperature and its confidence interval overlapped zero (Table 1).

Endemic species richness was not modeled well by the candidate hypotheses. The best-ranked model was the null model containing only an intercept (Table 1). The second-ranked model, within a ΔAICc of 2, was for the mid-domain effect. The MDE model had the highest R^2 (.14) of the candidates and was positively related to endemic species richness (Figure 3d). The unstandardized slope of this model, however, deviated from the expectation of a 1:1 relationship ($b = 0.27 \pm 0.33$; Figure 3d).

Finally, there was no evidence for a positive correlation between species elevational ranges and elevational midpoints, as Rapoport's

rule would predict. The Pearson's correlation coefficient was $-.16$, $-.12$, $-.27$, and $-.22$ for all reptiles, snakes, lizards, and endemics, respectively. All correlations were insignificant ($p > .6$ in all cases).

4 | DISCUSSION

Our study is the first analysis of reptile diversity along an elevational gradient within the Western Ghats. We found a linear decline in reptile richness with increasing elevation (Figure 2a). This pattern is repeated in lizards (Figure 2c), who make up the largest fraction of overall reptile diversity in this area, but not for snakes or endemic species (Figure 2b,d). We find no clear relationships between snake and endemic species richness with elevation. Furthermore, our data do not support a range of spatial hypotheses concerning the underlying drivers of reptile species richness (i.e., low R^2 s and high ΔAICc s of these models; Table 1, Table S3). Instead, our data suggest that temperature is the primary factor driving the diversity of reptiles in this area.

Our headline result is the monotonic decline in reptile and lizard species richness, which appears to be driven by temperature (Table 1). Fewer reptiles (and lizards) are found in the colder, high elevations (Figure 2). These findings echo results from both the global and the local scale. For example, McCain (2010) found that the most common richness–elevation pattern in reptiles across the globe was a monotonic decline, and this was largely explained by temperature. Similar findings have been reported for Himalayan reptiles (Chettri et al., 2010), the Costa Rican herpetofauna (Fauth et al., 1989), reptiles in the Dinaric Alps (Kryštufek et al., 2008), and a suite of other ectotherms from around the globe (Bishop et al., 2014; Peters et al., 2016). Although negative richness–temperature relationships are reported for many taxa, including endotherms such as birds and bats (McCain, 2007, 2009), a monotonic decline pattern is most reported for ectothermic taxa (McCain, 2010). Consequently,

TABLE 1 Results of modeling to test hypotheses of species richness drivers

Taxon subset	Explanatory variable	Slope 1	Slope 2	AICc	ΔAICc	R^2
Reptiles	Temperature	4.27 ± 1.54		72.08	0	.73
	Temperature + tree density	4.87 ± 2.07	0.91 ± 2.07	74.97	2.9	.73
	Area	2.52 ± 2.65		87.39	15.31	.2
Snakes	Null			55.89	0	0
	Temperature	0.48 ± 1.13		58.39	2.49	-.01
	Tree density	0.09 ± 1.17		59.33	3.44	-.09
Lizards	Temperature	3.63 ± 0.99		59.78	0	.83
	Temperature + tree density	3.45 ± 1.38	-0.26 ± 1.38	63.61	3.83	.82
	Tree density	-2.54 ± 1.9		78.11	18.33	.36
Endemics	Null			57.93	0	0
	MDE	0.9 ± 1.12		58.14	0.21	.15
	Tree density	-0.7 ± 1.18		59.51	1.58	.06

Note: For each taxonomic subset, summaries of the top three linear regression models are shown. AICc is the bias-corrected Akaike information criterion. ΔAICc is calculated relative to the top-ranked model for each taxonomic subset. R^2 is adjusted R^2 . Standardized slopes are also given \pm the 95% CIs. Slope 1 refers to the first or only explanatory variable. Slope 2 refers to the second, where applicable, which is always tree density.

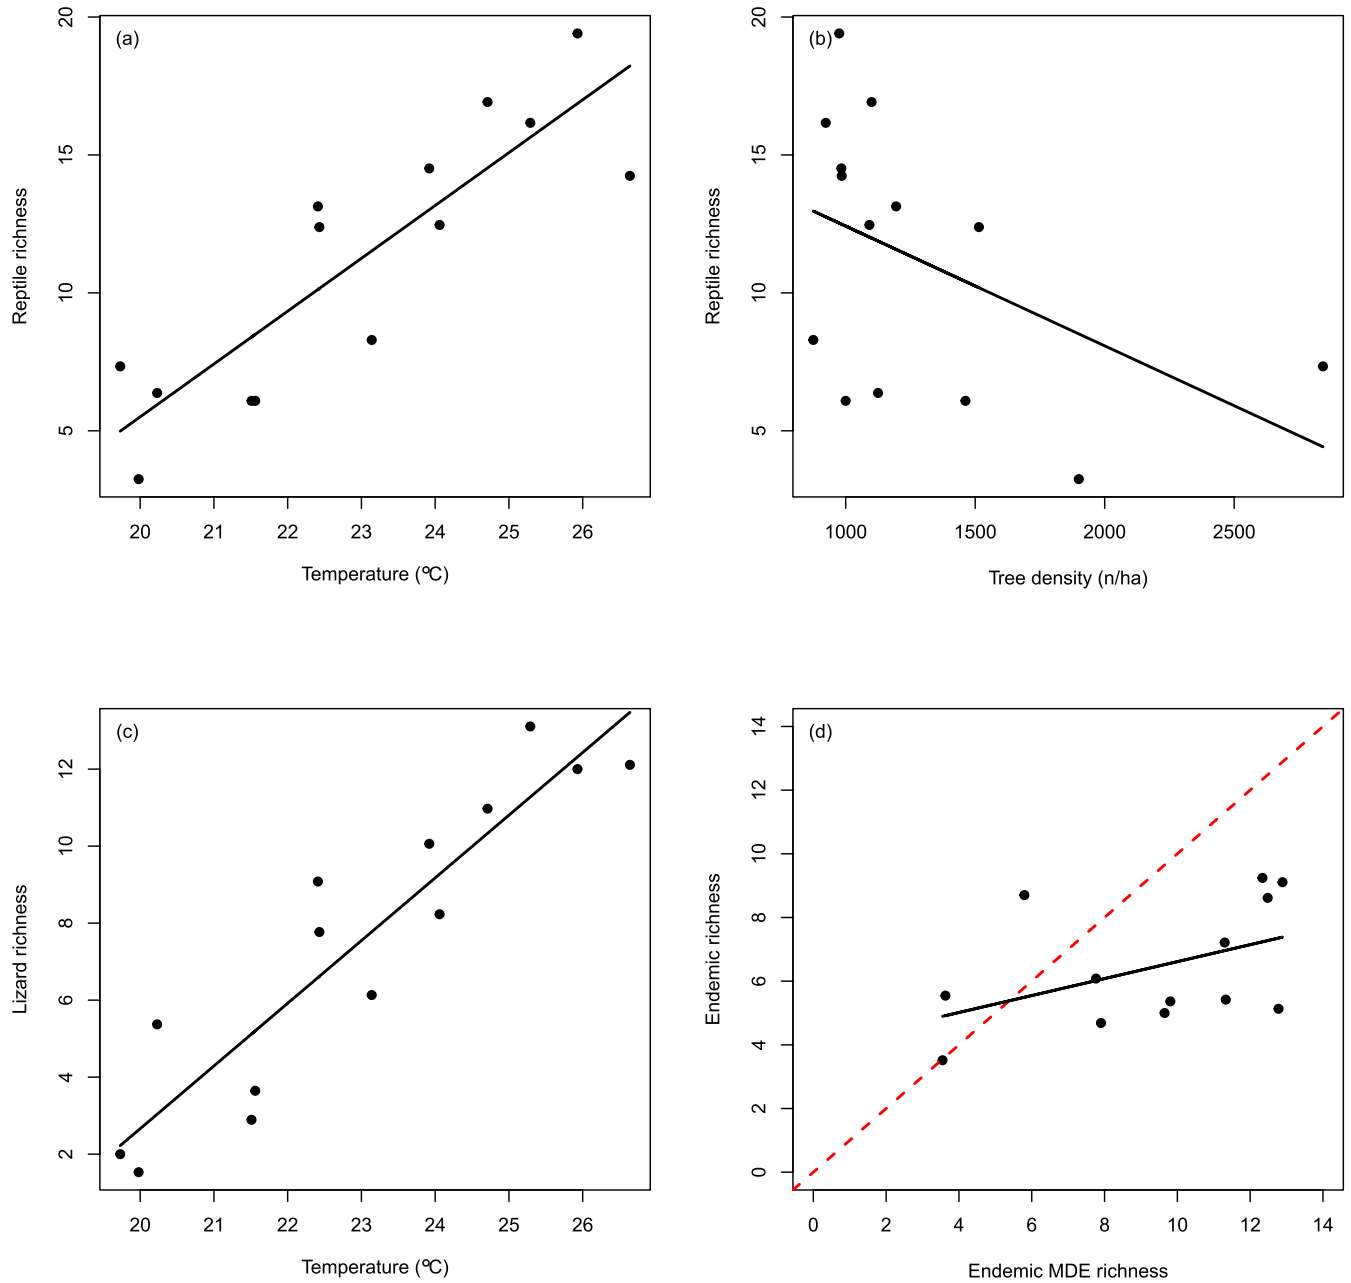

FIGURE 3 Select relationships between species richness of different reptile subsets and potential drivers. Reptile richness in relation to temperature (a) and tree density (b) lizard richness in relation to temperature (c) endemic richness in relation to the MDE predictions (d). Data points are elevational sampling sites. Black solid lines represent linear regression lines. Red dashed line in (d) represents a 1:1 relationship, which would be expected if the mid-domain effect (MDE) predictions of species richness match observed richness patterns. Relationships displayed here were top-ranked by AICc, or within Δ AICc of the top-ranked models and are displayed here for illustration

our results in the Western Ghats feed into the general narrative that temperature is the primary driver of reptile species richness gradients worldwide.

Despite this overall finding, however, we do not detect any systematic patterns in snake or endemic richness patterns. For snakes, at least, this may be a consequence of our sampling. Compared with lizards, snakes are rare and can be difficult to observe during VES. This results from their cryptic behaviors, frequent use of inaccessible microhabitats (e.g., burrows, boulders, and tree holes), and low

rates of activity (Durso et al., 2011; Parker & Plummer, 1987). In our dataset, 40% of snake species were recorded at only a single site, whereas this was the case for only 12% of lizards. This high proportion of singleton observations suggests that this sampling difficulty may well be obscuring any systematic patterns in snake richness. Consequently, we suggest that further standardized and repeated sampling across the Western Ghats is needed to fully disentangle the issue of snake elevational diversity patterns in the region. Note, even at a global scale, data scarcity is a major issue in deriving broad-scale

diversity patterns in snakes and in assessing their conservation status or extinction risks (Böhm et al., 2013, 2017).

In terms of endemic species, this potential sampling issue is unlikely to explain our results. Of the species we sampled, 53% were endemic, which closely matches the proportion of endemic reptiles in the Western Ghats, which is 47% (Srinivasulu et al., 2014), and only 20% were found at a single site. Consequently, we are more confident that the patterns we describe for endemic species are reflecting reality—that the number of endemic species does not systematically vary across elevation. An interesting contrast with endemics can be seen in frogs from the Hengduan Mountains, China. In this case, endemics were not influenced by environmental factors but did fit MDE predictions (Fu et al., 2006). While we do not find strong evidence that endemic species follow the MDE, our data agree with those of Fu et al. (2006) in that the diversity patterns of endemic species do not appear to be driven by bioclimatic variables.

How representative are our results in the Agasthyamalai Hills of the Western Ghats as a whole? The Western Ghats largely consist of conical shaped mountains, as do the hills sampled here (Elsen & Tingley, 2015). Compared with the windward side we focused in the present study, the ranges toward the leeward side of the Ghats slightly differ in their habitat types and rainfall intensities (Nair & Daniel, 1986; Nair, 1991), but are unlikely to differ in their temperature–elevation patterns. Critically, the unique high-elevation tropical montane cloud forest known as Shola, a natural matrix of forests and grasslands (found only above 1,400 m a.s.l.), is scarce in the Agasthyamalai landscape compared with most of the northern hill ranges (e.g., Anaimalai Hills—2,695 m a.s.l.) (Robin & Nandini, 2012). Sholas are known for the presence of some endemic reptiles (Deepak & Vasudevan, 2008), and this has been further proved by recent discoveries (Deepak et al., 2020). Consequently, studies exploring such high-elevation habitats could alter the endemic–elevation pattern that we see here. Finally, a recent phylogeographic analysis of frogs highlighted that the Palghat Gap (a natural biogeographical barrier within the Western Ghats) could potentially be a barrier to dispersal and influence larger macroevolutionary patterns (Vijayakumar et al., 2016). Whether this biogeographical barrier also causes differences in the patterns and drivers of reptile richness, however, remains to be tested—we suspect that it is unlikely.

In this study, we have not analyzed beta diversity across elevation because our sampling effort differed across the gradient. For alpha diversity (species richness), we could correct for this using known interpolation and extrapolation techniques (Hsieh et al., 2016). While similar corrections exist for beta diversity (Chao et al., 2005), this is beyond the scope of the current manuscript. Regardless, there is a clear opportunity and need for more comparative analyses of elevational patterns (including beta diversity) between different ranges within the Western Ghats. Regardless, considering the largely similar habitat types across the region and the repeated temperature–elevation gradients, we suggest that our alpha diversity analyses are likely to be representative of the entire Western Ghats.

In summary, we provide the first evidence of reptile species richness–elevation patterns in the Western Ghats, a global biodiversity hot spot. Despite the strong geometric constraints (mountain summit and coastline) present in the study range, the observed richness patterns were not shaped by the mid-domain effect or the available area effect in the Agasthyamalai Hills. Temperature is the clear driver of these patterns for reptiles, and lizards but not for snakes and endemic species. These temperature relationships result in a monotonic decline in reptile and lizard richness with increasing elevation. These findings agree with those at the global scale, which report a tight link between temperature and reptile diversity patterns (McCain, 2010). Since external temperatures directly determine metabolic rates in ectotherms (such as reptiles and amphibians), they show higher affinities with temperature and are more vulnerable to changing climates than endotherms (i.e., birds and mammals) (Rolland et al., 2018). This becomes a critical issue for a large number of range-restricted reptiles in the Western Ghats where many species are endemic and confined to certain hill ranges. As global temperatures rise, these species may find themselves pushed to new elevational ranges, or they may run out of appropriate thermal environments entirely (Colwell et al., 2008). The next steps are to extend this kind of standardized sampling, throughout the Western Ghats, to confirm whether the patterns are repeatable and to further generalize our understanding of how biodiversity is maintained in these ancient landscapes.

ACKNOWLEDGMENTS

This publication is an outcome of a larger project on reptiles and birds in the Agasthyamalai Hills, Western Ghats, funded by the Department of Biotechnology (DBT), Govt. of India (Grant No. BT/PR-13769/BCE/08/803/2010). We dedicate this paper to late S. Bhupathy of SACON who was the principal investigator of this project and PhD supervisor of J.V.J initially. We are grateful to Kerala Forest Department for all the research permissions (Letter No.WL 10/1540/2012) and logistic support in the field. We thank Director, SACON, for the support at different stages of the study. Special thanks to P.V. Karunakaran, SACON, for his help in vegetation sampling. Nathan J. Sanders, University of Vermont, USA, gave comments on earlier drafts of the MS and facilitated collaborations. We thank Arun P. R, SACON and Bhoj K. Acharya, Sikkim University, for the guidance and constant support to J.V.J. We appreciate the help provided by the field assistants and local communities during the field study.

AUTHOR CONTRIBUTION

J.V.J conceived the questions and designed the study. J.V.J and M.P conducted field data collection. J.V.J and T.R.B designed the manuscript, carried out data analysis, and led the writing. R.J and M.P provided feedbacks for improving the manuscript at different stages. All authors contributed to the final draft.
